Motivated by CoNb_2O_6 (belonging to the columbite family of minerals), we theoretically study the physics of quantum ferromagnetic Ising chains coupled anti-ferromagnetically on a triangular lattice in the plane perpendicular to the chain direction. We combine exact solutions of the chain physics with perturbative approximations for the transverse couplings. When the triangular lattice has an isosceles distortion (which occurs in the real material), the $T = 0$ phase diagram is rich with five different states of matter: ferrimagnetic, Néel, anti-ferromagnetic, paramagnetic and incommensurate phases, separated by quantum phase transitions. Implications of our results to experiments on CoNb_2O_6 are discussed.

Two of the most exciting themes in condensed matter physics are the destruction of magnetic order at absolute zero temperature, *i.e.* quantum criticality [1], and quantum fluctuations in geometrically frustrated magnets. Each of these themes has its archetype: the quantum Ising chain in a transverse field [1] for quantum criticality, and the triangular lattice Ising model for geometrical frustration [2]. Remarkably both these ideals are combined in CoNb_2O_6 , a material which may be understood as a collection of weakly coupled Ising chains that sit on a triangular lattice in the plane perpendicular to the chain direction. Very recently, CoNb_2O_6 has been the subject of beautiful single crystal inelastic neutron scattering experiments by Coldea *et al* [3]. The observed spectrum has been shown to reflect some very subtle properties of one-dimensional Ising quantum critical physics, that were discovered three decades after the study of the quantum Ising chain was initiated [4], in a triumph of theoretical physics led by Zamolodchikov [5]. A full interpretation of the experimental data requires an understanding of the interplay of quantum criticality in the chain and the physics of frustration in the plane perpendicular to the chain. In this paper, we combine the remarkable insights of Zamolodchikov with the novelty that frustration brings to the phase diagram of this remarkable material, setting up a platform to understand the experimental data in totality. Our focus here is to chart out the global phase diagram of CoNb_2O_6 , as well as other less well studied materials that have similar structures.

CoNb_2O_6 is an insulator. A strong single ion anisotropy forces the spin on the magnetically active Co^{2+} ($3d^7$) ions to point either “up” or “down” along the local easy axis, realizing a two-level system. The Co^{2+} ions interact with each other through Ising interactions of the form $S_i^z S_j^z$, where $\vec{S}_i$ are the usual spin-1/2 operators acting on the two level system located at site i . A magnetic field applied along the b-axis is transverse to all the easy axes and hence may be modeled by a term, $h_\perp S_i^x$, which acts like a transverse field on the Ising spins. In the absence of the transverse field the exchange interactions will cause the Ising spins to order magnetically. On the other hand when $h_\perp$ is much larger than the exchange interactions, the Ising spins will all lie in the quantum superposition, $(|\uparrow\rangle + |\downarrow\rangle)/\sqrt{2}$, highlighting the fact that the transverse field is a quantum mechanical parameter with no classical analogue. The central question of interest that we will address in this publication is: What is the nature of the magnetic ordering and what is the sequence of $T = 0$ phases between the two extreme limiting cases as $h_\perp$ is tuned?

We begin by presenting a minimal theoretical model for CoNb_2O_6 which incorporates details of the columbite structure and which we expect to reproduce most of the features of the experiments. The lattice consists of zig-zag chains of Co^{2+} ions with a strong ferromagnetic Ising interaction, $J_0 < 0$ along the c-direction. The chains form an isosceles triangular lattice in the a-b plane, with anti-ferromagnetic coupling to neighbors of strength J_1 and J_2 as shown in Fig. 1.

$$H = J_0 \sum_{\mathbf{r}} S_{z;\mathbf{r}}^z S_{z;\mathbf{r}+\mathbf{a}_1}^z + J_1 \sum_{\mathbf{r}} S_{z;\mathbf{r}}^z S_{z;\mathbf{r}+\mathbf{a}_2}^z + J_2 \sum_{\mathbf{r}} S_{z;\mathbf{r}}^z S_{z;\mathbf{r}+\mathbf{a}_3}^z + J_2 \sum_{\mathbf{r}} S_{z;\mathbf{r}}^z S_{z;\mathbf{r}+\mathbf{a}_3}^z - h_\perp \sum_{\mathbf{r}} S_{z;\mathbf{r}}^x, \quad (1)$$

$\mathbf{a}_{1,2,3}$ are the three nearest neighbors on the triangular lattice illustrated in Fig. 1. Motivated by CoNb_2O_6 we focus on the limit when $0 < J_1, J_2 \ll |J_0|$, the limit of weakly coupled Ising chains. Our focus is on the effects of quantum fluctuations controlled by the transverse field and hence we will not address early experimental work [6, 7] which studied the material in a longitudinal field. Our results with some modifications also apply to other materials which are known to realize Ising spin chains weakly coupled on a triangular lattice [8]. Theoretically, a study of the

2-dimensional triangular Ising anti-ferromagnet in a transverse field is available [9], which corresponds to the limit of $J_0 = 0$ of our model. We are interested in the opposite limit in this paper. Were $\alpha \equiv J_2/J_1 = 1$, the system would form a perfect triangular lattice in the basal plane. It is known that the material has $\alpha \lesssim 1$ and hence the coupling along the chains running along the x-axis is a little stronger [6]. As we shall see, the lattice anisotropy significantly enriches the phase diagram.

When $J_1, J_2 = 0$ the model Eq. (1) reduces to a collection of one-dimensional Ising chains in a transverse field (TFIC),

$$H_{\text{TFIC}} = J_0 \sum_i S_i^z S_{i+1}^z - h_\perp \sum_i S_i^x - h_\parallel \sum_i S_i^z. \quad (2)$$

An $h_\parallel$ term is included even though we study the model Eq. (1) with no parallel field; the reason for this will become clear below. The TFIC harbors a quantum critical point (between a magnetic and a paramagnetic state when $h_\parallel = 0$ and $h_\perp = J_0/2$) in the same universality class as the well studied two-dimensional Ising field theory. Indeed, the singular contribution to the ground state energy of the TFIC Hamiltonian, Eq. (2) can be related to the free energy of the Ising field theory by a simple re-scaling of variables. The scale is set by comparing correlation functions in the TFIC (it can be solved exactly when $h_\parallel = 0$, see *e.g.* [10]) to the Ising field theory results [11]. We find,

$$E_{\text{TFIC}} = \frac{J_0}{2} \mathcal{E}_{\text{IFT}} \left(\frac{h_\perp - J_0/2}{J_0/2}, \frac{c_h h_\parallel}{J_0/2} \right). \quad (3)$$

We will make use of the scaled variables $\bar{h}_\perp = \frac{h_\perp - J_0/2}{J_0/2}$, $\bar{h}_\parallel = \frac{c_h h_\parallel}{J_0/2}$ and express all energies in units of $J_0/2$ ($c_h = \sqrt{\frac{e^{1/4} 2^{1/12}}{4A^3}} \approx 0.4016$, $A \approx 1.2824$ is Glaisher's constant). Expansions for the function $\mathcal{E}_{\text{IFT}}(\bar{h}_\perp, \bar{h}_\parallel)$ are available [11] in different limits for both finite $\bar{h}_\perp$ and $\bar{h}_\parallel$, when $\xi = \bar{h}_\parallel/\bar{h}_\perp^a \ll 1$ and when the magnitude of $\eta = -\bar{h}_\perp/\bar{h}_\parallel^{1/a}$ is small,

$$\begin{aligned} \mathcal{E}_{\text{IFT}}^{\bar{h}_\perp > 0}(\bar{h}_\perp, \bar{h}_\parallel) &= \frac{\bar{h}_\perp^2}{8\pi} \log \bar{h}_\perp^2 + \bar{h}_\perp^2 (G_2 \xi^2 + G_4 \xi^4 + G_6 \xi^6 \dots), \\ \mathcal{E}_{\text{IFT}}^{\bar{h}_\perp < 0}(\bar{h}_\perp, \bar{h}_\parallel) &= \frac{\bar{h}_\perp^2}{8\pi} \log \bar{h}_\perp^2 + \bar{h}_\perp^2 (\tilde{G}_1 |\xi| + \tilde{G}_2 |\xi|^2 + \dots), \\ \mathcal{E}_{\text{IFT}}(\bar{h}_\perp, \bar{h}_\parallel) &= \frac{\bar{h}_\perp^2}{8\pi} \log \bar{h}_\perp^2 + \bar{h}_\parallel^{16/15} \left[-\frac{\eta^2}{8\pi} \log \eta^2 + (\Phi_0 + \Phi_1 \eta + \Phi_2 \eta^2 + \dots) \right], \end{aligned} \quad (4)$$

where $a = 15/8$ is a critical index of the Ising universality class. The numbers G_n , $\tilde{G}_n$ and Φ_n are universal numbers which are known to great accuracy, a few are reproduced in Table I.

In order to expand around the non-trivial TFIC limit we construct a variational wave-function, $|\Psi\rangle = \prod_i |\bar{h}_i\rangle$, as a product of TFIC ground states, where the longitudinal field $\bar{h}_\parallel = \bar{h}_i$ defining the TFIC Hamiltonian for each chain is taken as a variational parameters. The variational energy for our model is given by,

$$E_{\text{mf}} = \sum_i \mathcal{E}_{\text{IFT}}(\bar{h}_\perp, \bar{h}_i) + \bar{h}_i \bar{m}_i + \sum \bar{m}_i \frac{\bar{J}_{ij}}{2} \bar{m}_j, \quad (5)$$

where the magnetization on the i^{th} chain, $\bar{m}_i = -\partial \mathcal{E}_{\text{IFT}} / \partial \bar{h}_i$. Optimization over $\bar{h}_i$, gives $\bar{h}_i = -\bar{J}_{ij} \bar{m}_j$

$$E_{\text{mf}} = \sum_i \mathcal{E}_{\text{IFT}}(\bar{h}_\perp, \bar{h}_i) - \sum \bar{h}_i \frac{\bar{J}_{ij}^{-1}}{2} \bar{h}_j. \quad (6)$$

Here the labels i, j span sites in a plane (or corresponding chains), and J_{ij} is the interaction between a pair of spins. In addition we have defined the rescaled matrix $\bar{J}_{ij} \equiv c_h^2 J_{ij} / (J_0/2)$, whose non-zero entries are $\bar{J}_{1,2} = c_h^2 J_{1,2} / (J_0/2)$. Sometimes we prefer to work with the mean-field magnetization, $\bar{m}_i = \bar{J}_{ij}^{-1} \bar{h}_j$, in which case $E_{\text{mf}} = \sum_i \mathcal{E}_{\text{IFT}}(\bar{h}_\perp, -\bar{J}_{ij} \bar{m}_j) - \sum \bar{m}_i \frac{\bar{J}_{ij}}{2} \bar{m}_j$. The philosophy of our approach is similar to ‘‘chain mean-field’’ theories that has been applied to a number of unfrustrated problems [12, 13, 14].

We now study the quantum phase diagram (phases and phase transitions) that arise by extremizing the variational energy Eq. (5) using the exact expansions Eq. (4) for the TFIC. We present our results for the phase diagram as a functions of $\bar{J}_1$ and $\bar{h}_\perp$, for a fixed α .

Perfect Triangles: When $\bar{J}_2 = \bar{J}_1$ (*i.e.* $\alpha = 1$), we have perfect equilateral triangles in the basal plane. Treating this coupling in perturbation theory, we approach the magnetic ordering from each of the two phases of the Ising chain, the paramagnetic phase for $\bar{h}_\perp > 0$ and the magnetic phase for $\bar{h}_\perp < 0$.

When $\bar{h}_\perp < 0$, each isolated chain has a two-fold degenerate magnetic state. Once the chains are coupled this degeneracy is lifted by the exchange fields from the neighbors. Working perturbatively, we expand the energy Eq. (6) order by order in $\bar{J}_1$ till the degeneracy is fully lifted. At leading order after minimizing the energy with respect to the magnitude of $\bar{m}_i$, $E_{\text{mf}} \approx \bar{m}_i \frac{\bar{J}_{ij}}{2} \bar{m}_j$, (with $|\bar{m}_i|$ fixed) i.e. we obtain the classical triangular lattice Ising model for the signs of $\bar{m}_i$. It is well known that there is an extensive degeneracy of configurations which minimize the energy[2], i.e. ground states consist of all configurations with exactly one pair of parallel spins ($\bar{m}_i$ of the same sign) on each elementary triangle. We must continue expanding in $\bar{J}_1$ to find how this entropy is finally lifted. At next order, the free energy receives a contribution, $\delta E_{\text{mf}} \approx \tilde{G}_2 \sum_i |\bar{h}_\perp|^{2-2a} (\bar{J}_{ij} m_j)^2$. Since $\tilde{G}_2 < 0$, this perturbation prefers to have spins on all elementary hexagons parallel. So finding the quantum ground state of our model when $\bar{h}_\perp < 0$ is reduced to finding the classical ground state of the model, $H = J \sum_{\langle ij \rangle} \sigma_i \sigma_j - K \sum_i (\sum_a \sigma_{i+e_a})^2$ where e_a are all the neighbors of a site, when $K, J > 0, K \ll J$ and $\sigma_i = \pm 1$. We find that the ground state (proven in 1A) is a three-sublattice ferrimagnetic state with spins pointing up on the A sub-lattice and the spins pointing down on the B and C sub-lattices (there are a total of 6 symmetry-related states). We denote this state as **FR**, see Fig. 2.

When $\bar{h}_\perp > 0$, the isolated chains are in a non-degenerate gapped paramagnetic (**PM**) state. Perturbation theory in the coupling $\bar{J}_1$ leaves this state stable and hence there is always a region of **PM** for small enough $\bar{J}_1$. We can now ask if we increase $\bar{J}_1$ what magnetic order will first condense. The primary condensation takes place at $(4\pi/3, 0)$. Since the order parameters are small, in this regime we can perform a Landau expansion for the order parameter. We have to consider both the complex order parameter at $\mathbf{Q}_c = (4\pi/3, 0)$ which we call Φ and the real uniform component at $(0, 0)$ which we call m : $h_i = \Phi e^{i\mathbf{Q}_c \cdot \mathbf{r}} + \Phi^* e^{-i\mathbf{Q}_c \cdot \mathbf{r}} + m$. Keeping only the terms relevant to our study from the most general expansion for these two fields, we arrive at the following Landau continuum expression for the energy density $E_{\text{mf}} \approx \int d^2 r \epsilon_L$, ignoring gradient terms,

$$\epsilon_L = \alpha_\Phi |\Phi|^2 + \beta_\Phi |\Phi|^4 + \alpha_m m^2 + \lambda_3 m(\Phi^3 + \Phi^{*3}) + \lambda_6(\Phi^6 + \Phi^{*6}) \quad (7)$$

The coefficients are fixed by the parameters, $G_2, G_4, G_6, \bar{h}_\perp$ and $\bar{J}$. As $\bar{J}_1$ is increased, the condensation of Φ takes place when $\alpha_\Phi = 0$ (note however α_m remains non-zero) in Eq. (7), when $\bar{J}_1^c = \frac{1}{6|G_2|} \bar{h}_\perp^{2a-2}$. We can then optimize m for a given configuration of Φ , $m = -\lambda_3 / (2\alpha_m) (\Phi^3 + \Phi^{*3})$ and eliminate it from the energy. This shifts the λ_6 term to $\lambda_6 - \lambda_3^2 / (4\alpha_m)$, which evaluates to $\frac{3G_2 G_6 - 8G_4^2}{3G_2} \bar{h}_\perp^{2-6a} > 0$ at the critical point. This favors states in which Φ^6 is real and negative, so that the phase θ defined by $\Phi = |\Phi| e^{i\theta}$ is pinned to $\pi/2$. Magnetic order with $\Phi = |\Phi| e^{i\pi/2}$ and $m = 0$ corresponds to an anti-ferromagnetic state, we call **AF**, illustrated in Fig. 2 (b). This establishes that the **AF** order forms first when the critical $\bar{J}_1^c$ is crossed.

The pattern of magnetic ordering close to $\bar{h}_\perp = 0$ can be found using the η -expansion. In this regime, we find with $\eta = 0$ that the **FR** state has the lowest energy and this state can be smoothly connected to the state found for $\bar{h}_\perp < 0$.

Putting together the results from the three expansions, when $\bar{h}_\perp > 0$, $\bar{h}_\perp < 0$ and $\bar{h}_\perp = 0$, we find that the simplest form of the phase diagram consistent with these expansions is the one shown in Fig. 3(a). On general grounds, the transition between **FR** and **AF** can either be direct and first-order, or it may proceed through a region of “coexistence” corresponding to states with complex Φ^6 .

Isosceles Triangles: Now we adapt and extend the above analysis to the more complicated case when $\alpha = \bar{J}_2 / \bar{J}_1 \neq 1$, resulting from an isosceles distortion of the triangular lattice in the basal plane (as occurs in the real material).

When $\bar{h}_\perp < 0$, once again there is a macroscopic degeneracy associated with the spontaneous symmetry breaking on each chain which will be lifted by the $\bar{J}_{1,2}$ interactions. Exactly as in the $\alpha = 1$ case, at leading order, we have an Ising model for m_i , but now on an anisotropic lattice, $E_{\text{mf}} = \bar{m}_i \frac{\bar{J}_{ij}}{2} \bar{m}_j$. For $\alpha > 1$ the ground state is a two-fold degenerate Néel state (**N1**), shown in Fig. 2. For $\alpha < 1$ (the case in CoNb_2O_6), the situation is more complicated, and at leading order the ground state still has a degeneracy. The triangular lattice in the basal plane can be divided into “basal” chains (not to be confused with the c-axis Ising chains), see Fig. 1, each of which is Néel ordered, however each basal chain can be shifted by a unit without lifting the degeneracy. In fact, in mean field theory this sub-extensive degeneracy is not lifted at all, an artifact of this approximation. Instead, a full perturbative expansion splits the degeneracy at fourth order (see Appendix IB), by creating a ferro-magnetic interaction between alternate basal Néel chains (even and odd basal chains get locked separately). This effective interaction is a quantum fluctuation effect, not present in the classical $\bar{h}_\perp = 0$ limit. The phase shift between even and odd basal chains is determined spontaneously and leads to an extra 2-fold degeneracy, resulting in a 4-fold degeneracy for the **N2** state. For a fixed $\bar{h}_\perp < 0$ and $1 - \alpha \ll 1$, for arbitrarily small $\bar{J}_1$, we have shown that the **N2** state is selected. If $\bar{J}_1$ is made large enough however one expects a transition back into the **FR** state. The phase boundary between **N2** and **FR** is first order, and can be estimated by asking how big $\bar{J}_1$ should be so that the $\delta E_{\text{mf}} \approx \tilde{G}_2 \sum_i |\bar{h}_\perp|^{2-2a} (\bar{J}_{ij} m_j)^2$ (derived above for $\alpha = 1$) term that picks the **FR** state is large enough to close the gap that the anisotropy opens; we find $\bar{J}_1^{\text{N2-FR}} = \frac{\bar{h}_\perp^{2a-2}(1-\alpha)}{2|G_2|((1+2\alpha)^2-3)}$.

When $\bar{h}_\perp > 0$, we proceed as in the case of perfect triangles. For small $\bar{J}_1$ the **PM** state is stable. However, at sufficiently strong coupling there is again a condensate but it occurs at an *incommensurate* wave-vector. The onset wave-vector is determined completely by α , it is $(q_x^*, 0)$, where $q_x^* = 2\cos^{-1}(-\frac{\alpha}{2})$, shifted from $(4\pi/3, 0)$. The phase transition will occur again when the coefficient of the quadratic term of the $(q_x^*, 0)$ boson mode changes sign, this determines the critical coupling: $\bar{J}_1^c = \frac{\bar{h}_\perp^{2a-2}}{2|G_2|(2+\alpha^2)}$. We call this phase with incommensurate magnetic ordering **IC**. As $\bar{J}_1$ is made even stronger the system will eventually prefer to lock-in to a commensurate ordering vector. For $1 - \alpha \ll 1$, this state will be the **AF** state discussed above. To understand the commensurate-incommensurate phase transition, it is convenient to begin in the commensurate $\mathbf{Q}_c = (4\pi/3, 0)$ **AF** phase. We can then understand the transition to the incommensurate state as the formation of a dilute condensate of domain walls (which separate the 6 degenerate minima). We begin by evaluating the mean-field energy, for configurations of the form $\bar{h}_i = |\Phi| [e^{i(\mathbf{Q}_c \cdot \mathbf{r}_i + \theta(\mathbf{r}_i))} + \text{c.c.}] + m$, where $\theta(\mathbf{r})$ is a smooth field which creates a domain wall when it shifts between domains, $\theta = (2\pi/6)n$. Owing to the anisotropy of the problem, we may assume that (apart from fluctuations), $\theta(\mathbf{r})$ depends only upon x . After coarse-graining and extremizing with respect to m , we then obtain the famous sine-Gordon model [15],

$$E_{\text{sg}} = A_{yz} \int dx \left[\frac{\kappa}{2} (\partial_x \theta)^2 + \delta_x \partial_x \theta + \lambda \cos(n_{\text{sg}} \theta) \right], \quad (8)$$

where A_{yz} is the sample area in the $y-z$ plane, and the couplings of the SG model can be related to the parameters in Eq. (6) as worked out explicitly in Appendix IC; $n_{\text{sg}} = 6$. From these expressions, we can calculate the phase boundary between the commensurate **AF** state and the **IC** state at leading order in $(1 - \alpha)$: $\bar{J}_1^{\text{CIT}} = \bar{J}_1^c + \mathcal{A}_{\text{CIT}} \bar{h}_\perp^{2a-2} (1 - \alpha)$, where $\mathcal{A}_{\text{CIT}} = \frac{G_4 \pi}{-2G_2 \sqrt{16G_4^2 - 6G_2 G_6}}$ is a pure number.

Our arguments above have predicted a phase diagram shown in Fig. 3 when $1 - \alpha \ll 1$. As expected from scaling arguments, all the phase boundaries scale as $\bar{J} \approx \mathcal{A} \bar{h}_\perp^{2a-2}$ when the TFIC's are close to their individual critical points, where $\mathcal{A}$ is an amplitude which depends on the transition being considered. We have succeeded in computing the amplitudes, $\mathcal{A}$ in some rather non-trivial approximations which we have detailed in the body of the work. Since $\alpha \lesssim 1$ in CoNb_2O_6 , our results should apply to this material. Let us now turn to a discussion of the experimental response of each the phases as $\bar{h}_\perp$ is increased from zero and to the nature of the phase transitions between them.

Néel phase: This is the phase **N2** (illustrated in Fig. 2) which appears with weak external fields. It has no net magnetization and exhibits an elastic neutron peak at momentum $(\frac{\pi}{2}, 0)$ ($(0, \frac{1}{2}, 0)$ in the orthorhombic co-ordinate system). This is in agreement with zero field experiments[6, 7], though further-neighbor interactions not present in our model could play a role at $h_\perp = 0$.

Ferri-magnetic phase: As $\bar{h}_\perp$ is increased, we expect a first order phase transition into the **FR** state. The transition **N2-FR** is driven by the increase of quantum fluctuations of the Ising spins. The **FR** phase has a net uniform magnetic moment and thus is characterized by elastic neutron peaks both at zero momentum and at the commensurate ordering vector $(4\pi/3, 0)$. As $\bar{h}_\perp$ is increased we expect the **FR** order to weaken causing a reduction of the Bragg peaks; the uniform magnetization m and hence zero momentum peak goes to zero as $\bar{h}_\perp$ is increased much faster (like the third power) than the peak at $(4\pi/3, 0)$.

Anti-Ferromagnetic phase: The **AF** state also orders at $(4\pi/3, 0)$, but it has no uniform component of the magnetization in the z -direction and is hence analogous to an anti-ferromagnet. It is entirely different from the **N2** state however, and is truly a result of the geometric frustration present. The difference between the **AF** and **FR** states could be probed by tilting the field in the $b-c$ plane – one expects a weak first order transition at zero tilt in the **FR** case but not the **AF** one.

Incommensurate: As $\bar{h}_\perp$ is increased further still, there is a transition into the **IC** phase that is driven by a condensation of domain walls in the **AF** phase. The **IC** phase is characterized by a dense set of Bragg peaks and a massless goldstone (phason) mode. The primary ordering vector, q_x , shifts continuously in this phase from $q_x = 4\pi/3$ in the **AF** phase to value $q_x^* = 2\cos^{-1}(-\alpha/2)$ at the transition to the **PM**, the evolution of $q_x(\bar{h}_\perp)$ is described in ID).

Paramagnetic: Finally when the quantum fluctuations due to $\bar{h}_\perp$ are strong enough, magnetic ordering is completely suppressed and the system enters a quantum paramagnetic phase. This state is gapped and breaks no symmetries of the model, Eq. (1).

Quantum Phase Transitions: There are four quantum phase transitions that we have predicted in the evolution of phases as $\bar{h}_\perp$ is tuned. Although the location of these transitions relies on mean field theory, their critical properties are universal. The first transition between **N2-FR** is expected to be strongly first-order. The second transition is between the **FR-AF** states. It can take place either by a direct first order transition or through a coexistence of the two phases. Within mean field theory, we find the latter, though this conclusion may be sensitive to the approximation, and to small perturbations of the Hamiltonian. The third transition between the **AF-IC** state is continuous and is of the commensurate-incommensurate type. We have calculated the leading singularity of the ordering vector here.

The final and fourth transition is between **IC-PM**, which we expect to be in the XY universality class in 4 classical dimensions. Since this is at the upper critical dimension we expect mean field exponents with log corrections. The transverse magnetization as a function of the external field, $h_\perp$, should provide a good method for locating the phase transitions. The magnetization itself should have discontinuities at the first order transitions and its first derivative should have singularities at the locations of the second order transition.

In summary, we have studied the model, Eq. (1), for CoNb_2O_6 in an external magnetic field that is aligned along the crystallographic b-axis, which results in a fully quantum mechanical “transverse field”. Application of the transverse field drives the frustrated Ising model under study into a number of fascinating phases through quantum phase transitions. We have outlined the basic properties of each of these phases here. Detailed calculations of the excitation spectrum, measurable by neutron scattering, are also possible, and will be presented in a follow-up publication. An interesting question we leave for future exploration is the nature of the finite-temperature phase diagram of this model.

I. SUPPLEMENTARY MATERIALS

A. Ground state for $\alpha = 1$ and $\bar{h}_\perp < 0$

Here we prove that the ground state of the model on the perfect triangular lattice, $H = \bar{J} \sum_{\langle ij \rangle} \sigma_i \sigma_j - K \sum_i (\sum_a \sigma_{i+e_a})^2$, for $\bar{J}, K > 0$ and $K/\bar{J} \ll 1$ is the **FR** state. The proof is as follows: We need to find which Ising configuration has the lowest energy with the K term. Lets imagine an Ising configuration on an infinite lattice with f_6, f_5, f_4, f_3 the fraction of sites that have 6, 5, 4, 3 anti-parallel neighbors. Then $f_6 + f_5 + f_4 + f_3 = 1$. Also a third of the bonds have to be frustrated (host parallel spins) in any Ising configuration which implies, $f_5 + 2f_4 + 3f_3 = 2$. The contribution of the K term to the energy in this language is: $E = -K(36f_6 + 16f_5 + 4f_4)$. Since we have two extra equations, and four unknowns, we can rewrite the equation for E completely in terms of f_3 and f_6 , obtaining $E = -K(4 + 8(f_3 + f_6))$. Since $f_3 + f_6 < 1$, the lowest energy is clearly obtained only with 3, 6 sites. This configuration has $f_6 = 1/3$ and $f_3 = 2/3$. The only such configuration is the ferri-magnetic state described above.

B. Ground state for $\alpha < 1$ and $\bar{h}_\perp < 0$

In the section we show that the ground state when $\alpha < 1$ and when the chains are magnetically ordered is the **N2** state for arbitrarily small inter-chain coupling. The goal here is to develop a systematic perturbative expansion about the limit of decoupled Ising chains. On the magnetic side there is a huge degeneracy in this limit because each chain can have its magnetization m_i point up or down. Working in imaginary time, we can set it up as follows,

$$\frac{Z}{Z_0} = \frac{\int e^{-S_{1d} - S_c}}{\int e^{-S_{1d}}} = \langle e^{-S_c} \rangle, \quad (9)$$

where $S_c = \int d\tau S_i^z(\tau) \frac{\bar{J}_{ij}}{2} S_j^z(\tau)$ and all averages are taken over the decoupled limit. Note that in the zero temperature limit, the partition function is simply given by, $Z = e^{-\beta E_{\text{gs}}}$. We can calculate the average perturbatively using the cumulant expansion,

$$\langle e^{-S_c} \rangle = e^{-[\langle S_c \rangle - \frac{1}{2!} \langle S_c^2 \rangle_{\text{con}} + \frac{1}{3!} \langle S_c^3 \rangle_{\text{con}} - \frac{1}{4!} \langle S_c^4 \rangle_{\text{con}} + \dots]}, \quad (10)$$

where the subscript “con” indicates that we should only keep connected averages. When we have to evaluate the connected averages we can factor the average into products of averages each of which acts within a single chain, since the chains are decoupled at 0th order. For an odd number of spins, these single chain averages will be replaced by, e.g. $\langle S_i^z(\tau) \rangle \rightarrow \bar{m}_i |\langle S^z(\tau) \rangle|$ with $\bar{m}_i = \pm 1$. Then we can ask which configuration of $\bar{m}_i$ produces the lowest energy and keep evaluating higher order contributions till any “accidental” degeneracy is completely lifted. The coefficients of the interactions between $\bar{m}_i$ are determined by integrals over correlation functions of the d=1 Ising chain.

We now turn to an evaluation of this approach for the case of interest, when $\alpha < 1$. *At leading order*, we have the term $\bar{m}_i \frac{\bar{J}_{ij}}{2} \bar{m}_j$, which gives Néel configurations along the stronger bonds that form a chain in the basal plane (not to be confused with the Ising chains in the transverse direction!), but each basal chain can be translated by a unit leading to a $2^{N_{\text{chain}}}$ degeneracy (sub-extensive entropy). We expect that the degeneracy is lifted by locking-in of spins on alternate basal chains, but we still need to determine whether the locking-in is ferromagnetic or anti-ferromagnetic.

At second order, we generate ferro two-spin interactions between alternate basal chains $\propto -\bar{J}_{ij}\bar{J}_{ik}\bar{m}_j m^k$ but it is easy to see that these cancel when summed over the sites of the basal chain due to the Néel order, *i.e.*, the mean field from all the sites in a chain add up to zero. The degeneracy is not lifted at this order. At third order, we generate both two-spin and four-spin couplings. It turns out that both the two- and four-spin couplings cancel out. At fourth order, we have a large number of generated two-spin couplings and four-spin couplings. Turns out that the four-spin coupling does not lift the degeneracy, but a careful summation of the 86 two-spin couplings does! The two-spin interactions at fourth order are ferromagnetic and hence alternate chains are locked ferromagnetically as shown in Fig. 2.

C. Commensurate-Incommensurate Transition

In this section we calculate the energy of a domain wall in the commensurate order parameter as a function of the external parameters. The simplest commensurate-incommensurate transition (CIT) occurs when single domain walls condense [15], *i.e.* when the energy of a single domain wall goes to zero. We can estimate this by a calculation of the domain wall energy. A domain wall corresponds to a spatial profile of the phase $\theta(\mathbf{r})$ of the complex order parameter Φ introduced earlier in the context of Eq. (7). We hence consider the following form for the field $\bar{h}_i$ at site $\mathbf{r}_i$,

$$\bar{h}_i = |\Phi| \left[e^{i(\mathbf{Q}_c \cdot \mathbf{r}_i + \theta(\mathbf{r}_i))} + \text{c.c.} \right] + m. \quad (11)$$

Here, $\mathbf{Q}_c$ is a commensurate wave vector $(4\pi/3, 0)$ and $\theta(\mathbf{r})$ is a slowly varying functions of $\mathbf{r}$. We substitute this expression into our variational energy, Eq. (5) and then derive a coarse grained energy density for the field $\theta(\mathbf{r})$. Next we integrate out m , like we discussed below Eq. (7), arriving at the Sine-Gordon long-wavelength energy for θ , Eq. (8), where we have:

$$\begin{aligned} \lambda_6 &= \frac{-8G_4^2 + G_2G_6}{G_2} \bar{h}_\perp^{2-6a}, \\ \lambda_3 &= -8G_4 \bar{h}_\perp^{2-4a}, \\ \alpha_m &= -3G_2 \bar{h}_\perp^{2-2a}, \\ \lambda &= 2|\Phi|^6 \left(\lambda_6 - \frac{\lambda_3^2}{4\alpha_m} \right), \\ \kappa_x &= -|\Phi|^2 G_2 \bar{h}_\perp^{2-4a}, \\ \delta_x &= -|\Phi|^2 \frac{2G_2(1-\alpha)}{\sqrt{3}} \bar{h}_\perp^{2-2a}. \end{aligned}$$

Except for δ_x , we evaluated all these couplings with $\alpha = 1$.

Now we are all set to calculate the transition from the state with commensurate $(4\pi/3, 0)$ ordering to the incommensurate phase. Since the δ term has only an x gradient, we will look for solutions that are translationally invariant in the y -direction, dropping all derivatives in this direction. Noting that δ only gives a boundary term, it may be expressed simply as the winding number $N_w = [\theta(x=L) - \theta(x=0)] \frac{1}{2\pi/6}$, the number of times the field θ moves from one its six minima to an adjacent one. The solution for $N_w = \pm 1$ is well known,

$$\theta(x) = \frac{4}{n} \tan^{-1} \left(e^{\pm n_{\text{sg}} \sqrt{\frac{\lambda}{\kappa_x}} (x-x_0)} \right), \quad (12)$$

where $n_{\text{sg}} = 6$ in our case.

The energy of a single domain wall is positive for $|\delta| < |\delta_c| = 4\sqrt{\kappa_x \lambda}/\pi$, and the wave vector is commensurate. For $|\delta| > |\delta_c|$, domain walls condense and the wave vector is incommensurate. In order to compute the phase boundary, we need the magnetization for a given $\bar{h}_\perp$ and $\bar{J}_1$ close to the transition when $\alpha = 1$. Within our chain-MFT we can compute this by optimizing the mean-field energy. We find,

$$|\Phi|_{\alpha=1}^2 = \frac{h_\perp^{4a-2}}{36G_4} \frac{\bar{J}_1 - \bar{J}_1^c}{\bar{J}_1 \bar{J}_1^c} \quad (13)$$

where $\bar{J}_1^c = h_\perp^{2a-2}/(6|G_2|)$. Now using this as input we can calculate for $1-\alpha \ll 1$ the commensurate-incommensurate phase boundary. We find at leading order in $(1-\alpha)$:

$$\bar{J}_1^{\text{CIT}} = \bar{J}_1^c + \mathcal{A}_{\text{CIT}} \bar{h}_\perp^{2a-2} (1-\alpha) \quad (14)$$

where $\mathcal{A}_{\text{CIT}} = \frac{G_4 \pi}{-2G_2 \sqrt{16G_4^2 - 6G_2 G_6}}$ is a pure number.

FIG. 1: Schematic structure of Co^{2+} ions in CoNb_2O_6 . Ising spins localized on each Co^{2+} form ferromagnetic chains running along the c -direction; J_0 is the strength of the exchange along these c -axis chains. In the basal a - b plane perpendicular to the c -axis, the chains form a triangular lattice. The stronger anti-ferro J_1 bonds parallel to the b -axis divide the basal triangular lattice into “basal chains” (marked with thick black lines), the weaker anti-ferro $J_2 = \alpha J_1$ bonds (marked with thin green lines) connect neighboring “basal chains”. $1 - \alpha \ll 1$ in CoNb_2O_6 is a measure of the departure from a perfect basal triangular lattice in this material.

D. Ordering vector in the IC

Once the $\bar{h}_i$ condense, initially at some incommensurate vector q_x^* , it is clear that the ordering vector will change continuously in the **IC** phase as $\bar{h}_\perp$ is tuned. We can calculate the evolution of the ordering vector from q_x^* by performing a harmonic expansion valid close to the transition. Approaching the **IC** phase at high $\bar{h}_\perp$ from the **PM** state, we look for mean-field solutions including a higher harmonic, $\bar{h}_i = \Phi_k e^{ik \cdot r_i} + \Phi_{3k} e^{i3k \cdot r_i} + \text{c.c.}$, which minimize the energy, Eq. (5). We can write the energy density as, $e = \alpha_k |\Phi_k|^2 + u_k |\Phi_k|^4 + \alpha_{3k} |\Phi_{3k}|^2 + \lambda_k (\Phi_k^3 \Phi_{3k}^* + \text{c.c.})$. Optimizing over Φ_k and Φ_{3k} , we find that minimum energy density is $e = -\frac{\alpha_k^2}{4u_k} - \frac{\lambda_k^2}{\alpha_{3k}} \left(\frac{-\alpha_k}{2u_k} \right)^3$. If $\lambda_k = 0$ then the optimal $k = q_x^*$, but in practice there is a shift, that to leading order in $(1 - \alpha)$ and $\bar{h}_\perp - \bar{h}_\perp^c$ is given as,

$$\delta q_x = \frac{32(2a - 2)^2}{9\sqrt{3}} (1 - \alpha) \left(\frac{\bar{h}_\perp - \bar{h}_\perp^c}{\bar{h}_\perp^c} \right)^2 \quad (15)$$

from which we conclude that the shift is positive for $(1 - \alpha) \ll 1$.

We now turn to the opposite edge of the **IC** phase, when it borders a commensurate phase, *i.e.* the **AF** phase where the ordering takes place at $(4\pi/3, 0)$. Once we cross into the **IC** phase the finite density of domain walls shifts the ordering vector. The shift is given by $\delta q_x = 2\pi n_d$, where n_d is the linear density of domain walls. In order to estimate n_d , we write an expression for the energy of a lattice of domain walls including an interaction energy between domain wall pairs from the SG model (assuming $n_d w \ll 1$),

$$\frac{E_{\text{sg}}(n_d)}{A_{yz}} \approx \left(\frac{8\sqrt{\kappa\lambda}}{n_{\text{sg}}} - \frac{2\pi\delta_x}{n_{\text{sg}}} \right) n_d + U n_d e^{-\frac{1}{wn_d}}, \quad (16)$$

where $U > 0$ is the strength of repulsion between domain walls and $w = \frac{1}{n_{\text{sg}}} \sqrt{\frac{\kappa}{\lambda}}$ is the width of domain walls and controls the range over which they interact. When $\delta_x > \delta_c = 4\sqrt{\kappa\lambda}/\pi$, there is a finite density of domain walls, $n_d^* \sim \frac{1}{w \ln[\delta_c - \delta_x]}$. From this we can estimate the leading singularity in the shift in the ordering vector close to the CIT,

$$\delta q_x = \frac{-2\pi}{w \log[\bar{h}_\perp - \bar{h}_\perp^{\text{CIT}}]} \quad (17)$$

where w is the width of the domain wall at the CIT. From our derived expressions Eq. (12) for the coupling constants in the SG model, we can calculate the leading dependence of the domain wall width at the CIT, we find, $w = \frac{2\sqrt{3}}{\pi(1-\alpha)n_{\text{sg}}}$. A plot of the two asymptotes for the ordering vector is shown in Fig. 4.

FIG. 2: Magnetic ordering patterns of **FR**, **AF**, **N1** and **N2** phases. (a) Dividing the lattice into A, B and C sub-lattices (marked red, blue and black), the **FR** phase corresponds to putting the spins on two of these parallel and the spins on the third anti-parallel, leading to a six-fold degeneracy. (b) The **AF** state is also a three sub-lattice state but with the spin $\langle S_i^z \rangle$ on one site fluctuating to zero (c) the two-fold degenerate **N1** phase, obtained when $\alpha > 1$, can be thought of most simply as the bi-partite (red and blue) Néel phase obtained when the J_1 bonds are set to zero. (d) the four-fold degenerate **N2** phase obtained when $\alpha < 1$ corresponds to a Néel ordering along the basal chains (J_1 bonds) and a ferromagnetic locking of alternate chains (shown by dashed lines).

	$n = 1$	$n = 2$	$n = 3$
G_{2n}	-1.84522	8.33370	-95.1689
$\tilde{G}_n$	-1.35783	-0.0489532	0.0387529
$\tilde{\Phi}_{n-1}$	-1.19773	-0.318819	0.1108915
